Abstract

Catechol-O-methyltransferase (COMT) is one of the cardinal enzymes in the degradation of catecholamines and levodopa. Genetic variants of the COMT gene may affect COMT enzyme activity. The most examined COMT gene polymorphism is the nonsynonymous single nucleotide polymorphism (SNP) in exon 4 (Val108/158Met; rs4680). This highly functional polymorphism is responsible for fourfold variations in enzyme activity and dopamine catabolism. Recent data suggested that even synonymous SNPs of the COMT gene can lead to changes in enzyme activity. Genetically determined COMT activity can affect an individual's response to levodopa therapy and carries the risk of complications from prolonged levodopa use in Parkinson's disease (PD) patients. Identifying at-risk individuals through genetic susceptibility markers could help to prevent the development of levodopa-induced complications in PD.

Key words: Parkinson's disease, levodopa-induced dyskinesia, hallucinations, COMT gene, single nucleotide polymorphisms, Val158Met (rs4680)

doi.org/10.5937/arhfarm74-45472
Introduction

Parkinson's disease (PD) is a progressive disabling disorder caused by the degeneration of dopaminergic nigrostriatal pathways. It is clinically manifested by the presence of motor (bradykinesia, resting tremor, rigidity, and postural instability) and non-motor symptoms (cognitive decline, behavioral disturbances, autonomic dysfunction, sleep disorders) (1). The dopamine precursor, levodopa, has remained the most effective symptomatic therapy in PD since its introduction (2). Acute side effects of levodopa, such as nausea, vomiting, anorexia, and hypotension, commonly recede after 2 to 3 weeks of drug use (2). However, prolonged treatment with levodopa and disease progression lead to several motor and non-motor complications (2). About 40-50% of PD patients medicated with levodopa develop motor complications, such as motor fluctuations and dyskinesias, 4-6 years following the introduction of levodopa (3). Psychotic symptoms occur in about one-third of PD patients on dopaminergic therapy, usually ten or more years after diagnosis, and significantly impair the quality of life of these patients (4).

Disease progression parameters and clinical variables do not explain inter-individual heterogeneity in response to levodopa, suggesting a complex pathomechanism involving genetic factors. Pharmacogenetics aims to identify genetic factors that could be responsible for variability in treatment response, as well as for the occurrence of complications of chronic dopaminergic therapy. Polymorphisms in various genes implicated in dopamine metabolism and transport have been studied concerning the side effects of prolonged use of levodopa in PD patients, and the COMT gene is one of the most examined genes.

Thus, we performed this review to critically discuss current findings and how polymorphisms of the COMT gene may affect the treatment response and levodopa-induced complications such as motor fluctuations, dyskinesias, hallucinations, and psychosis in PD patients. An extensive literature search for English-language clinical trials was performed using MEDLINE (through PubMed up to April 2023) and EMBASE databases. The search terms were: "Parkinson's disease," "levodopa-induced dyskinesia," "hallucinations," "catechol-O-methyltransferase" or "COMT polymorphism," "single nucleotide polymorphisms," and "Val158Met (rs4680)". We have also searched manually to identify any studies potentially omitted by the database search. We (BR and MS) independently reviewed the titles and abstracts. The inclusion criteria were cross-sectional or longitudinal, the study group were idiopathic PD patients, genetic factors were any SNPs of the COMT gene, outcomes were dose-response, motor fluctuation, dyskinesia, hallucinations, and psychosis, and patients were treated with chronic dopaminergic agents (levodopa, dopamine agonists, MAO-B inhibitors and COMT inhibitors). References of reviewed articles and meta-analyses were also checked. The systematic search procedures used are shown in Figure 1.
The human COMT gene is localized on the long arm chromosome 22 at the gene map locus of 22q11.2. It consists of six exons (the first two non-coding) and two promoters, P1 and P2, which control expression and are located in exon 3 (5). The COMT gene encodes two known isoforms of the COMT enzyme: the shorter, soluble, or cytosolic isoform (S-COMT) and the membrane-associated isoform (MB-COMT) (5, 6). MB-COMT is located in almost all parts of the human central nervous system (CNS). At the same time, S-COMT predominates in most other tissues except the brain (7). COMT enzyme degrades catecholamines, including dopamine and levodopa.

SNP rs4680 polymorphism is the most considered COMT gene polymorphism found in the 4th exon of the COMT gene. The substitution of valine (Val) to methionine (Met) at position 158, i.e., the replacement of G>A (Val158Met), leads to greater thermolability of the enzyme, resulting in approximately 30% lower enzyme activity. Val with Met can be replaced in the S-COMT but at position 108 (8, 9). COMT genotype distribution varies by ethnic origin. About 25% of Caucasians are homozygous for the low activity variant (Met/Met; AA), 25% are homozygous for the high activity variant (Val/Val; GG), and the remaining ones have the intermediate activity variant (Val/Met; AG) (7). AA genotype COMT is present in only 10% of the Asian population. The SNP rs4680 COMT gene has been linked to differences in cognitive abilities (specifically in tasks involving executive functions), mood, pain perception, and response to physical or
emotional stress (8-10). It has been shown that carriers of the GG genotype have an increased risk of developing schizophrenia (6) and a weaker response to olanzapine therapy (11).

However, it has been recognized that the haplotype formed by the four SNPs of the COMT gene (rs6269, rs4633, rs4818, and rs4680) has been affected to a greater extent on enzyme activity compared to a single rs4680 polymorphism (12). Therefore, the ACCG, ATCA, and GCGG haplotype carriers have low, medium, and high COMT activity, respectively (12).

Recent data suggested that synonymous SNPs of the COMT gene (i.e., rs165728 and rs174699) impact mRNA structure and stability and decrease COMT activity (13).

**The association of therapeutic response to levodopa treatment and COMT gene SNPs**

There are appreciable inter-patient and intra-personal distinctions in the response to levodopa. Genetic variations in the COMT activity contribute to different individual levodopa responses. It could be expected that carriers of the low COMT activity genotype would show a more significant response to levodopa than those with other genotypes. However, studies have shown that different COMT genotypes (14, 15) did not affect the duration or extent of response to a single levodopa dose in PD patients. Bialecka et al. found that daily doses of levodopa were significantly higher for GCGG COMT haplotype carriers (rs6269-rs4633-rs4818-rs4680) (16). A recent case-control study investigated the association of eleven SNPs in the COMT gene and levodopa response in Chinese PD patients and found that patients with the TT genotype of rs165728 and TT of rs174699 required higher daily levodopa equivalent doses (LEDs) than the patients with CC and CT genotypes (13). Replacement of the T allele with C has been hypothesized to reduce COMT enzymatic activity, decreasing the needed levodopa doses (13). Though rs165728 is located in the 3’-UTR, and rs174699 is located in intron 5, they possibly alter mRNA structure and stability, decreasing COMT activity. In addition, Xiao et al. found that carriers of the T allele of rs4633 and A allele of rs4680 used higher daily LEDs (17).

**The association of motor complications of prolonged levodopa treatment and COMT gene SNPs**

PD patients frequently develop severe and often debilitating motor complications (motor fluctuations and dyskinesia) due to their prolonged therapy. The "wearing off" phenomenon is the predictable recurrence of PD symptoms ahead of the scheduled levodopa dose. The "on-off" phenomenon refers to sudden, sometimes unpredictable changes in PD symptoms, varying between the "on" state (phase of optimal drug action and motor improvement) and the "off" state (phase of returning PD symptoms after the expiration of therapy). Motor fluctuations most likely occur due to pharmacokinetic and pharmacodynamic factors associated with chronic levodopa use in the presence of severe nigrostriatal degeneration (1, 18).
The impact of COMT genotype on the risk of motor fluctuations has been investigated in several studies, with conflicting results (16, 19). A cross-sectional study among Chinese PD patients found that AA homozygotes had a lower risk of developing "wearing-off," suggesting that the rs4680 COMT gene might affect susceptibility to "wearing off" (20). However, a meta-analysis showed that allele A of rs4680 increased the risk of "wearing off" (21).

COMT inhibitors are considered the medication of choice for treating motor fluctuation by increasing the "on" state, decreasing the "off" state, and improving motor response (22, 23). Administration of levodopa with a COMT inhibitor maintains a permanent level of levodopa in the plasma and obtains uniform availability of levodopa in the brain. Few trials have examined the potential contribution of the COMT genotype in the clinical response to COMT inhibitors. Corvol et al. have shown that COMT polymorphism rules the acute response to COMT inhibitors (24). In this study, the GG rs4680 COMT gene genotype was associated with a prolonged entacapone-induced "on" state (24). However, other studies did not show variations in the therapeutic response and toxicity of COMT inhibitors among PD patients with different COMT genotypes. One longitudinal study found no association between rs4680 COMT and the duration of "on" and "off" states and disease severity in PD patients during two months of entacapone treatment (25). After entacapone therapy, the mean reduction in daily levodopa dose in each patient was significant in GG and AG carriers, but not in those with the AA genotype of the COMT gene (25). Kim et al. also showed that entacapone's efficacy and side effects did not differ among PD patients with different COMT genotypes (26).

Levodopa-induced dyskinesia (LID) or involuntary movements are usually clinically manifested as choreiform or dystonic movements and less frequently in ballistic movements and myoclonus. The most common LIDs are "peak dose," which occur when the concentration of levodopa in the blood is at its highest. Dyskinesias present during the entire duration of the levodopa effect are referred to as square wave dyskinesias (1, 18). Biphasic dyskinesias are less frequent and occur when plasma levodopa concentrations fall below or rise above the threshold for therapeutic efficacy. Finally, "off" dyskinesias happen when the concentration of levodopa in plasma is low and manifest through pain and cramps in the legs or foot dystonia. Clinical risk factors for LID include younger age at PD onset, greater severity, longer disease duration, length of levodopa treatment, and higher total levodopa dose (27, 28). However, it is still difficult to explain why dyskinesias do not appear in all patients medicated with high doses of levodopa for an extended period and sometimes occur in those exposed to relatively low levodopa daily doses in a short period (1).

The role of COMT gene polymorphisms as a vulnerability factor in LID onset has been explored to a great extent. Previous studies regarding the association of the rs4680 COMT gene polymorphism and LID have shown conflicting results. A prospective study conducted in the Netherlands found a twice higher risk among heterozygous PD patients and a 2.81 times higher risk of developing dyskinesia during levodopa therapy among AA carriers of the rs4680 COMT gene (19). A possible interpretation of this
result was that a higher incidence of dyskinesia occurred in patients with lower COMT activity due to exposure to higher doses of levodopa. In one study, the AA genotype was more common in patients with motor fluctuations ($p = 0.045$, OR= 3.82) or dyskinesia ($p = 0.030$, OR = 4.80) than in controls. Still, this finding was insignificant after Bonferroni’s correction (29). Sampaio et al. found that the COMT AA genotype (rs4680) was associated with the risk of LID after adjusting for sex and age (OR=5.53; 95%CI 1.5-20.1; $p=0.0009$) (30). A recent study that included 220 Brazilian PD patients found that AA genotype COMT had a 3.8-fold increased risk for LID development after Bonferroni’s correction (HR=3.841; 95% CI 1.29–11.37; $p=0.012$) (31). However, several other clinical studies have not verified the findings that a low-activity allele will have an increased risk of dyskinesia (14, 16, 32-35). The cross-sectional studies with Polish (16) and Italian PD patients (14) found no significant association between COMT polymorphism and LID, as well as the extensive survey of 1087 Chinese PD patients (30). The reviewed studies regarding the association between COMT polymorphism and LID demonstrated inconsistent results, which may be due to different ethnic groups, methodology used, and outcome definitions. The study with Chinese patients found that the GG genotype was more common in patients with motor fluctuations than in those without them (30). However, a meta-analysis involving 2385 PD patients implied that the AA rs4680 COMT may increase the risk of LID in a recessive genetic model for PD patients (36). Pooled ORs and 95% CIs suggested that the AA rs4680 COMT was associated with LID (OR=1.39, 95%CI:1.02–1.89, $p=0.039$) in the recessive model, and this correlation was more evident in Brazilian samples in the analysis stratified by ethnicity. Another recent meta-analysis on ethnicity showed that allele A rs4680 COMT is a risk factor for LID development in Asian PD patients. At the same time, using different genetic models, the GG genotype is a risk factor for LID development in non-Asian PD patients (37). Study design and small sample sizes led to the following essential limitations of the reviewed studies. Most of the studies are cross-sectional or retrospective, so they cannot be used to determine causality. Longitudinal studies with large samples would be preferable to provide insight into cause-and-effect relationships.

Ivanova et al. reported an association between four COMT SNPs (rs165774, rs4818, rs4633, and rs4680) and LID in 232 Caucasian PD patients (33). The rare allele of rs165774 was associated with an increased risk of dyskinesia (OR = 1.75; 95%CI 1.14-2.72), while in the case of rs4818, rs4633 and rs4680, the rare allele or homozygote genotype for the rare allele were protective against LID (OR = 0.57; 95%CI 0.34-0.92, OR=0.45; 95%CI 0.23-0.89 and OR=0.46; 95% CI 0.23-0.91, respectively), although the results did not reach statistical significance after adjusting for disease duration (33). No associations were found between combined BDNF (Brain-Derived Neurotrophic Factor) Val66Met, COMT Val158Met, and T941G MAO-A (Monoamine oxidase-A) SNPs and the prevalence or time to onset of LID in PD patients (32). A recent study found no individual associations of BDNF Val66Met, DAT (Dopamine Transporter) rs397595, and COMT rs4680 SNPs, but a potential combined impact of these polymorphisms on the occurrence of levodopa-induced motor complications (38). This
result implicated that a single SNP does not drive the event of motor complications. In addition, the phenotypic expressions of SNPs are probably affected by gene-gene interactions.

The association of non-motor complications of prolonged levodopa treatment and COMT gene SNPs

Hallucinations occur in about 8-40% of PD patients on chronic dopaminergic therapy, most often as visual hallucinations with preserved introspection in the initial stages and less frequently as auditory hallucinations (4). Besides hallucinations, the clinical range of psychotic symptoms in PD encompasses minor hallucinations (illusions, presence hallucinations, passage hallucinations) and delusions (4). The pathophysiology of psychotic symptoms in PD is complex and still insufficiently known. Prolonged dopaminergic therapy was long considered to be the primary risk factor for hallucinations in PD. Still, recent studies have shown that antiparkinsonian drugs alone are neither necessary nor sufficient to explain the onset of psychotic symptoms in all patients (39, 40). The appearance of psychotic symptoms in PD was related to older age, disease duration, cognitive disorders, depression, and sleep disorders (4).

Thus far, several attempts have assessed the impact of genetic factors on developing hallucinations in PD. A recent cross-sectional study, which included 234 PD patients, found no association between rs4680 of the COMT gene and psychotic symptoms in PD (41). This finding follows a retrospective postmortem study by Camicioli et al. (42) and another study by Creese et al. (43), which included demented PD patients. However, the survey by Radojević et al. showed that, in addition to well-established clinical risk factors for psychosis in PD (dopaminergic drugs, motor status, depression, and anxiety), the GG rs2734849 of the ANKK1 gene was a potential contributing factor (41). These results suggested that dopamine probably has a limited role in developing psychotic symptoms in PD compared to other neurotransmitters. Besides COMT, other genes might increase the risk of treatment complications (43). Moreover, the occurrence of levodopa nonmotor complications could be the result of gene-gene interactions. Namely, haplotypes of COMT and SLC6A3 were associated with the occurrence of visual hallucinations (AT vs. GC: OR=0.34; 95%CI=0.16-0.72; p=0.005) (44).

Table I summarizes studies examining the association of COMT gene polymorphisms with treatment response and levodopa-induced complications in PD patients.

**PD** - Parkinson's disease, **COMT** – catechol-O-methyltransferase, **SNP** – single nucleotide polymorphisms, **OR** - odds ratio, **CI** - confidence interval, **MAO** – monoamine-oxidase, **DRD2** - dopamine receptor 2, **BDNF** – brain-derived neurotrophic factor, **DAT** – dopamine transporter, **UPDRS** – Unified Parkinson's Disease Rating Scale, **LED** – levodopa equivalent doses, **VHs**= visual hallucinations

**Conclusion**

SNP rs4680 of the **COMT** gene has been considered the main reason for individual variation in human COMT activity. However, several studies have failed to demonstrate the relationship between treatment response, long-term levodopa complications, and rs4680 of the **COMT** gene, implying that a single SNP does not drive the event of difficulties. Additionally, interactions between SNPs likely affect mRNA structure and protein translation efficiency, all leading to changes in enzyme activity. Besides **COMT**, other genes affect individual response to dopaminergic drugs and the risk of treatment complications. Increased insight into how genetic variants affect response to levodopa could contribute to personalized antiparkinsonian therapy to maximize symptom control while minimizing severe side effects.
