ABSTRACT

This paper focuses on the voltammetric determination of lead, cadmium and zinc in water. Two ways of determining were investigated: individually and all three metals simultaneously. The experiments were performed using the Potentiometric Stripping Analysis (PSA). Determination of metals in real samples was preceded by preliminary tests. Preliminary investigations were performed in order to determine the optimal conditions of measurement. It was concluded that the process of determining was for most part influenced by: pH, time of metals extraction, stirring rate of the solution and the thickness of the mercury layer on the working electrode. The smallest concentrations of metals which can be determined using this method are: for lead $22.48 \mu\text{g dm}^{-3}$, for cadmium $16.23 \mu\text{g dm}^{-3}$ and for zinc $18.75 \mu\text{g dm}^{-3}$. The obtained results deviated from the actual 1.12% for lead, 1.91% for cadmium and 1.81% for zinc. All tests (individually and simultaneously) were conducted from model solution with concentration as follows: $44.96 \mu\text{g dm}^{-3}$ for lead, $32.47 \mu\text{g dm}^{-3}$ for cadmium and $37.50 \mu\text{g dm}^{-3}$ for zinc. The results of individual measurements deviated by 1.02% lead, 1.90% for cadmium and 1.89% for zinc. Simultaneously the contents were lower than real for: -4.58% for lead, cadmium for -1.91% and -1.89% for zinc. For the conditions determined, except for lead, deviations did not exceed $\pm 2\%$. This indicates that Potentiometric Stripping Analysis is a good way of individual and simultaneous determination of lead, cadmium and zinc and for determination of their concentrations in water (river and groundwater).

Keywords: Lead, Cadmium, Zinc, Potentiometric Stripping Analysis, Waters.

INTRODUCTION

Heavy metals are natural constituents of soil whence are due into waterways and via of plants and in the food chain (Kastori, 1997; Sekulić et al., 2003; Kastori et al., 2006). They are characterized by toxic effects which are manifested in traces. Testing area is the northern part of Kosovo and Metohija. This part is directly affected by 100 million tons of existing flotation landfills of Trepča, which occupy an area of about 350 ha. A voltammetric technique used to determine traces of heavy metals in the surrounding surface water (river) and groundwater (natural spring and borehole) was Potentiometric Stripping Analysis (Wang, 1985; Jin et al., 1997). Determination of metals, by a three-electrode electrolytic system, was preceded by reduction and oxidation processes. After reduction of metal ions on the working electrode, at a give potential, extracted metal ions are oxidized with oxygen from the solution and in terms of diffusion mass transfer they return to solution while monitoring the dependence of the potentials from oxidation time (Jagner, 1979; Marjanović et al., 1987; Riso et al, 1999;). This dependence is proportional to material concentrations. The potential of the working electrode does not change until the entire concentrations of the separate elements are oxidized. After complete oxidation of one, the working electrode potential increases to the

characteristic potentials at which oxidation of the following element takes place (Suturović, 1985; Suturović, 1992; Stanković et al., 2007; Suturović, 2003).

The aim of this study was: I) To establish conditions for the simultaneous determination of lead, cadmium and zinc using Potentiometric Stripping Analysis; II) Sampling and sample preparation as well as the reduction to a single sample is suitable for Potentiometric Stripping Analysis; III) Application of simultaneous Potentiometric Stripping Analysis for the determination of lead, cadmium and zinc in water samples.

EXPERIMENTAL

Apparatus

The tests in this paper were performed on the device for Potentiometric Stripping Analysis, Stripping analyzer M1 (Faculty of Technology in Novi Sad, Symmetry in Leskovac, Serbia). Basis of this system's functioning is a three-electrode electrolytic cell consisting of: disk working electrode of glassy carbon, the total area of 7.07 mm^2 , which is used as an inert carrier for the mercury layer; a reference silver-silver chloride electrode ($\text{Ag/AgCl/KCl/3.5 mol dm}^{-3}$) and a platinum auxiliary electrode. Metal content using Potentiometric Stripping Analysis were determined by standard addition method (Babincev, 2004).

* Corresponding author: ljiljana.babincev@pr.ac.rs

Reagents

All the solutions for the execution of this experiment were prepared from high purity chemicals (suprapur, Merck). The basic solutions were prepared by standard lead, cadmium, zinc and mercury (1.000 g dm^{-3}) while working solutions were prepared from the basic standards in the concentrations as follows: for the lead 90 mg dm^{-3} , zinc 75 mg dm^{-3} , for cadmium 65 mg dm^{-3} . In addition to standard solutions, the following ones were also used: hydrochloric acid (HCl, 30%), nitric-acid (HNO₃, 65%), di-methyl ketone (CH₃COCH₃, 99.5%), copper-sulfate (CuSO₄) and gallium-chloride (GaCl₃). The solutions were stored in polyethylene bottles (Babincev, 2004).

Sample preparation

Sample preparation for Potentiometric Stripping Analysis was done so that the certain amount of filtered water was evaporated after adding 5 ml of concentrated nitrate. The process was repeated three times in order to transform metals into the shape of ions. Following separation and evaporation, the dry residue was dissolved with 5 ml chlorine acid, and adding the ionized water, it has been transferred into the measuring pot of 100 ml. Aliquot of 20 ml has been transferred into the glass for electrolytic determination by Potentiometric Stripping Analysis (Babincev et al., 2011; Babincev, 2012a; Babincev, 2012b).

Procedure

Metal determination was preceded by the formation of the working electrode on the surface of glassy carbon from acidic solution of mercury(II)-ion concentration 10 mg dm^{-3} . Mercury film formation at glassy carbon electrode was performed at a constant current of $-48.90 \text{ } \mu\text{A}$ for the time of 240 s. In order to define optimal experimental conditions for determination of metals, the series of solutions (model solutions) of 20.0 ml of deionized water and 0.5–200 μl working standard solutions of lead, cadmium and zinc were prepared (Babincev, 2012c). Working standards were added to a micropipettes with variable volume of 0.10 (± 0.05) to 200 (± 1) μl . Extraction of lead, cadmium and zinc from prepared solutions was carried out at potentials of: -0.999 V for lead, cadmium to -1.106 V and -1.035 V for zinc. Simultaneous determination of all three metals was carried out at a negative potential (-1.400 V) compared to the potential of mercury that is positive (Babincev, 2012). The simultaneous determination of metals was performed after adjusting the pH and potential of separation (reduction) because in the analysis of strongly acidic solutions, for the reduction potential that is more negative than -1 V , it comes to hydrogen evolution at the working electrode. For these reasons, the value for the hydrogen evolution potential is increased for the overvoltage of hydrogen on the metals tested. Simultaneous determination of metals was carried out with prior addition of Ga(III)-ions, in order to prevent the formation of intermetallic compounds of zinc and possibly the present copper. Intermetallic

compound in the oxidation process leads to a decrease in signal for zinc, which depends on the ratio of copper and zinc. Studies were performed in model solutions with zinc concentrations of: 37.5, 187.5, and $375.0 \text{ } \mu\text{g dm}^{-3}$, and copper concentrations of 10.0, 20.0, 30.0 and $35.0 \text{ } \mu\text{g dm}^{-3}$. It was found that interference in the determination of zinc can come from the copper concentrations less than $10.0 \text{ } \mu\text{g dm}^{-3}$ with an error of up to 30%. By adding gallium of $40.0 \text{ } \mu\text{g dm}^{-3}$ in solutions containing copper from $35.0 \text{ } \mu\text{g dm}^{-3}$, for wider range of zinc concentration, the creation of their complex is prevented because more stable complex of gallium and copper is created.

In order to define the conditions of determination, the impact of the following was particularly examined: pH; stirring rate of solution, time of metals separation and time of working electrode formation.

After the conditions were established, the determination of lead, cadmium and zinc in real samples (river and groundwater) was performed.

RESULTS AND DISCUSSION

The influence of pH solution on the efficiency of determination was examined in the value range from 1.3–4.5 for metal concentrations of $224.30 \text{ } \mu\text{g dm}^{-3}$ lead, $162.01 \text{ } \mu\text{g dm}^{-3}$ cadmium and $375.00 \text{ } \mu\text{g dm}^{-3}$ zinc. It was found that the results obtained deviate by $\pm 2\%$ when the determination were performed from solutions pH 1.3, 1.6 and 2.0. The ratio of oxidation time and content, represented as a constant of Potentiometric Stripping Analysis ($\text{K/s dm}^3 \text{ mol}^{-1}$), has the highest value for lead when determination was performed from solution pH 1.6, for cadmium from solution pH 1.6 and 2.0, and for zinc from the solution pH 2.1–3.5. Simultaneous determination was performed at pH 2.1, because for a given value of pH constant of pH potentiometric stripping analyses for all three metals have the closest values (Fig. 1).

Figure 1. Dependence the constants Potentiometric Stripping Analysis for simultaneous determination of lead, cadmium and zinc by pH solutions

Effect of stirring rate on the determination of metals was investigated in the range of $1000 \square 6000 \text{ min}^{-1}$. The most efficient determinations have a stirring rate of 4000 min^{-1} , which can be explained by the optimal thickness of diffusion layer of ions in solution. Metal extraction was tested during periods of: 180, 240, 300, 360 and 420 s. The results of the determination

showed that the most efficient metal extraction is achieved for the period of 300 s. Contents extracted for the time deviate from the actual by: 1.05% for lead, 1.90% for cadmium and 1.94% for zinc. The least time necessary for metal extraction is 240 s, metal contents extracted for that time deviate from real by: 3.34% for lead, 3.00% for cadmium and 3.76% for zinc.

The impact of the mercury layer thickness on metal determination was analyzed as the time required for the formation of the working electrode. The working electrode formation was done by separating the mercury on glassy carbon within: 120, 180, 240, 300 and 360 s. A good reproducibility was obtained for all three ions when the mercury layer was formed within 240 s. The mercury layer formed in 240 s, based on reproducibility, provides a good homogenization of extracted metal ions, easier and faster dissolution process and better separation. In order to determine detection limits of

potentiometric analysis for lead, cadmium and zinc, solutions of 20.0 ml of deionized water and different working standard volumes from 0.5 to 600 μl were prepared. Metal extraction was performed within 300 s; solution stirring rate of 4000 min⁻¹ and the pH values were 1.6 for lead and cadmium and 2.1 for zinc. The results for the determination are presented in Tables 1-3.

Based on results presented, the minimum contents of lead, cadmium and zinc that were determined with an error of $\pm 2\%$ are: 22.48 $\mu\text{g dm}^{-3}$ of lead (determined with an error of 1.12%), 16.23 $\mu\text{g dm}^{-3}$ cadmium (determined with an error of 1.91%) and 18.75 $\mu\text{g dm}^{-3}$ zinc (determined with an error of 1.81%). In accordance with the standard deviations and the reproducibility, these contents can be considered the limits of determination. Standard deviations were 2.52 μg for lead, 1.56 μg of cadmium and 1.99 μg of zinc. The detection limit of Potentiometric Stripping Analysis for lead, cadmium and zinc is about 20 $\mu\text{g dm}^{-3}$. The highest concentrations that are determined by PSA with an error $\pm 2\%$ were: 2194.05 $\mu\text{g dm}^{-3}$ for lead; 960.12 $\mu\text{g dm}^{-3}$ for cadmium and 1312.50 $\mu\text{g dm}^{-3}$ for zinc. These contents were determined with the error of: -1.98% for lead, -1.93% for cadmium, and -1.95% for zinc and standard deviations of: 169.24 μg for lead, 68.73 μg for cadmium and 111.70 μg for zinc.

Simultaneous determinations

The determination of elements was studied simultaneously in 20.0 ml of deionized water and 10 μl working standard solutions of lead, cadmium and zinc, for metal concentrations of: 44.96 $\mu\text{g dm}^{-3}$ lead, 32.47 $\mu\text{g dm}^{-3}$ cadmium and 37.50 $\mu\text{g dm}^{-3}$ zinc. Results of this study have shown that potential of the working electrode for the simultaneous determination of lead, cadmium and zinc is 490–510 mV more negative than the potential of zinc dissolution (an element with the lowest redox potential). It was determined that all three elements can be determined at a negative potential (-1.400 V) in relation to the

potential of mercury that is positive. For that reason, values for extraction potentials are increased by hydrogen overvoltage on mercury, lead, cadmium and zinc. The simultaneous determination of lead and cadmium has shown optimal values for pH 1.6. For pH 2.1, cadmium and zinc were simultaneously determined. Simultaneous determination of lead and zinc was examined for pH 1.3, 1.6, 2.0, the most effective determinations were for pH 2.0. Zinc is most accurately determined for pH value of 2.3–3.5, which may partly be explained by the qualitative properties of zinc. The simultaneous determination of all three elements was performed (with the mentioned separation potential) for pH 2.1, because the constants of Potentiometric Stripping Analysis for this value were the closest.

With prior pH adjustment, metal content was determined by standard addition method. During the determination, metals are firstly reduced (separated) on working electrode and then (after electrolysis) they are oxidized (returned) to the solution. After returning to the solution, oxidation potential is registered, which is changed until the entire separated contents of one metal is returned to the solution. After returning one element to the solution, working electrode potential increases to characteristic potential at which oxidation of the following takes place. Results of simultaneous determination of lead, cadmium and zinc are given in Table 4.

^a X_s -concentration of the elements in the model solution, ^m X_i -measured concentration, ^b $\bar{X}$ -average measured concentration, number of measurements=5, ⁿ τ -time of oxidation, K_p -constant stripping analysis, ^c S -standard deviation, ^d K_v -coefficient of variation, ^e E_r -error determination

The obtained results suggest that there is a difference in the determinate contents when we take individual and simultaneous determinations into consideration. The results for the individual determinations deviated from the actual values by 1.02% for lead; 1.90% for cadmium and 1.89% for zinc. During the simultaneous determinations, the deviations were as follows: -4.58% for lead; -1.91% for cadmium and -1.89% for zinc. Results obtained for lead were less accurate. As it is about micro quantities, having in mind small standard deviations of simultaneous determination in relation to individual, simultaneous determination of these elements is considered possible. Potentiometric Stripping Analysis is applied in determination of heavy metals in samples of different nature (Kaličanin et al., 2001a; Kaličanin et al., 2001b; Kaličanin et al., 2001c; Suturović et al., 2001; Kaličanin et al., 2002). In this work, lead, cadmium and zinc in samples of waters are determined. The results for determination of the concentrations of lead, cadmium and zinc in river water (sampled successively every three months starting from april 2015 to february 2016) are shown respectively in Tables 5–8.

Table 5. The results of concentrations of lead, cadmium and zinc ($\mu\text{g dm}^{-3}$) in water of the river Ibar, april 2015

<i>MCL</i>	10.00	3.00	3000.00

The increase in lead content in these samples there was probably washing and filtration with a delay of those cities, and cities delays that are located upstream or on the bank of the Ibar. Near the *MCL* and the concentration of lead in the samples 3 and 5, which were taken from the measuring points are also close to the waste disposal. Lead is present in the water at the measuring point 1, which was chosen as the site of male pollution. How is this place located a few kilometers from the flows of the river Sitnica Trepčanska river and river Lushta into the river Ibar, and of all places of disposal of industrial waste, it can be assumed that the lead content in the sample contribute to exhaust fumes of motor vehicles on the road that passes by the banks of the Ibar River, as well as washing with asphalt street.

The minimum content of lead in the Ibar river water was found in the sample 2, which can be explained by the fact that

the sampling is done with the left bank of the Ibar river, opposite the city delay the Top Field. This measuring point is the furthest from the city traffic as a possible source of lead contamination. Increased concentrations of cadmium in the river water Ibar at the measuring points 3, 4, 5 and 6 above *MCL* is probably from the same causes as the increased concentration of lead. Sample 1 contains little cadmium. In sample 2 also has a low content of cadmium, but more than in a sample 1. This measuring point is the first in a series in which the mixed water of the river Ibar, Sitnica, Trepčanska river and Lushta, which are before the casting of the Ibar already polluted. The content of zinc, compared with *MCL* is significantly lower compared to lead and cadmium. As his low concentrations it can be said that the existing pollutants in the area tested not significantly affect the water pollution zinc. The results of the content of heavy metals in water samples taken at the same measuring points and in different seasons of the year have shown that there are certain differences, but it is noted the same trend of the contamination, that is determined by the measuring points are more polluted than the other.

The highest concentrations of lead in the samples from the measuring points 3, 4, 5, and 6 and the highest concentration of cadmium also at locations 3, 4 and 5. The results of determining the content of heavy metal in the spring and of Well water are shown in Tables 9–16.

Significantly, based on the result of determining that the concentration of lead in all the samples wells and water sources is less than the *MCL* for drinking water. Variations may occur in the lead content at the measuring point 10 (in the drilled wells in the village Grabovac), wherein the concentration i Increased content of lead probably arose due to the reduced quantity of water (drought) and the pumping raises the sediment and stirred with water, which was noticeable by the color of the sample.n the summer and autumn rather above the *MCL* of the drinking water (Službeni glasnik Republike Srbije, 1994). In the colder period of the year (autumn and winter) lead content is generally lower. Concentrations of cadmium and zinc in well and spring waters are also less than the Maximum allowable concentrations at all measuring points and in different seasons.

CONCLUSION

The objective of this study is simultaneous determination of lead, cadmium and zinc by stripping analysis, as well as application of the same in water analysis, establishment of determination conditions, extraction potential, extraction time, optimal solution stirring rate, pH, time of working electrode formation, as well as manner of samples preparation, using the approach of comparing the results of simultaneous with the results of individual determination. It is obvious that there is a

difference in results obtained. The efficiency of the individual determination was greater due to the better synchronization of the solution pH value and the extraction potential. Results accomplished in case of simultaneous determination have shown somewhat lower values which can be explained by the occurrence of hydrogen extraction in the analysis of acidic solutions, when extraction potential is more negative than -1 V. The maximum efficiency for all determinations was obtained at metal extraction time of 300 s, on electrode that is formed in 240 s and at solution stirring rate of 4000 min^{-1} . At higher stirring rates, the determination efficiency is reduced due to the decreased diffusion layer thickness. The lowest concentrations which can efficiently be determined by Potentiometric Stripping Analysis are: $22.48 \mu\text{g dm}^{-3}$ for lead, $16.23 \mu\text{g dm}^{-3}$ for cadmium and $18.75 \mu\text{g dm}^{-3}$ for zinc. Good efficiency is up to $2194.05 \mu\text{g dm}^{-3}$ for lead, $960.12 \mu\text{g dm}^{-3}$ for cadmium and $1312.50 \mu\text{g dm}^{-3}$ for zinc, which can be attributed to identical mechanism of mass transfer during extraction for the one during metal dissolution. For the simultaneous determination of all three metals, determination error was in range of 2–5%. The reproducibility of these measurements for lead, cadmium and zinc in the water samples ranged from: 10–13% for lead, 10–14% for cadmium and 8–9% for zinc. The obtained results indicate that Potentiometric Stripping Analysis is efficient in determination

of lead, cadmium and zinc, both individually and simultaneously, as well as in the analysis of water.
