ABSTRACT
Medical staff that makes the initial contact with patient with aortic dissection has a goal to rise a suspicion and recognize aortic dissection, as well as to safely transport the patient to a health center capable of providing the definite treatment. First step in the prehospital management is providing oxygen support via breathing mask to prevent organ damage. It is important to monitor all vital functions during transport, including heart rhythm and diuresis, in order to have a continuous insight into the patient's current state and in case of a deterioration react appropriately. Blood pressure control is the main goal of the medical treatment in aortic dissection. Systolic blood pressure should be kept between 100-120 mmHg, whereas the target heart rate is 60 beats per minute. Therapy should be started with intravenous administration of beta-blocker or non-dihydropyridine calcium channel blocker, followed by a vasodilator infusion. For pain management intravenous administration of opiates is recommended. In case of shock, intravenous fluid replacement with crystalloids should be initiated immediately, along with vasopressor therapy with noradrenalin or phenylephrine. In case of shock, the patient should be intubated and mechanically ventilated with the appropriate sedation.

Key words: aortic dissection, chest pain, prehospital care, medical therapy.

BACKGROUND
Although aortic dissection is not the most common condition in cardiology, its acute onset and high mortality rate require every health care provider to be familiar with the basic concept of its management. This is particularly important for the personnel that makes the initial contact with patient, whose goal is to rise a suspicion and recognize aortic dissection, as well as to safely transport the patient to a health center capable of providing the definite treatment.

CLINICAL PRESENTATION
Pain is the first and the most prominent symptom that occurs in over 90% of patients with aortic dissection.1, 2 The pain usually localized in the chest or in the back, it has a sudden onset and an intensive, tearing or ripping character.3 The pain can migrate along the spine towards the lower back as the dissection extends distally.4 The pain presentation can vary depending on the localization of the dissection (Table 1).

Table 1. Association between dissection localization and pain character

Considering the fact that such a severe pain can occur in a wide range of different acute conditions (Table 2), it is not a surprise that, in many cases, false diagnosis is made on initial contact with patient, out of which almost half is interpreted as acute coronary syndrome. The distinction between these two is that the pain in aortic dissection is strongest and most intensive at the very beginning, whereas ischemic pain usually progresses and intensifies over time.

Another common symptom in patients with aortic dissection is syncope, which usually indicates that the dissection has spread into the brachiocephalic trunk and carotid arteries. Other neurological symptoms may include paraplegia, vocal cord paralysis, and Horner’s syndrome.

The final diagnosis can only be made in hospital conditions using imaging techniques such as echocardiography, computerized tomography and magnetic resonance. Nevertheless, it is important to pay attention to particular signs in physical examination that can help in differential diagnosis of aortic dissection in prehospital conditions.

Hypertension is the most common sign in patients with aortic dissection. It is important to measure the blood pressure on both arms, because the specific sign for aortic dissection is the difference between left and right arm blood pressure of 20 mmHg or more. Every part of the body should be examined in search for signs of arterial insufficiency, primarily the absence of pulses. Auscultation should focus on search for diastolic murmur, which is a sign of aortic regurgitation that can develop with the dissection of the ascending aorta.

If possible, it is desirable to perform an ECG, mainly in order to exclude the acute coronary syndrome.

Blood pressure control is the main goal of the medical treatment in aortic dissection. Systolic blood pressure should be kept between 100-120 mmHg, whereas the target heart rate is 60 beats per minute. The ideal medication for reaching these parameters is beta-blocker, so the treatment should be initiated with intravenous administration of esmolol, metoprolol or labetalol. Caution should be taken when aortic regurgitation is present, because of the beta-blockers effect on diastole prolongation.

If there are contraindications for beta-blockers, or the desired heart rate reduction cannot be achieved, non-dihydropyridine calcium channel blockers verapamil or diltiazem can be administered.

If the blood pressure remains elevated despite the heart rate reduction, intravenous vasodilators, such as nitroglycerin, should be used. Most of the guidelines clearly point out that vasodilators should not be used before the target heart rate is achieved, because otherwise compensatory tachycardia may be induced, which would increase the stress on the aortic wall and cause the spreading of the dissection.
Alongside the blood pressure control, pain management is mandatory in the acute phase of aortic dissection. For this, intravenous administration of opiates is recommended. Morphine is the first choice, because it not only reduces pain, but also inhibits the sympathetic stimulation as well, which additionally reduces the stress on the aortic wall.3, 17

One should always have in mind the fact that every patient with an acute dissection of the aorta is likely to develop hemodynamic instability and eventually shock. If that occurs, intravenous fluid replacement with crystalloids should be initiated immediately. In case of a refractory hypotension despite the adequate fluid replacement, vasopressor therapy with noradrenalin or phenylephrine is indicated. Development of shock in patient with aortic dissection is a probable sign of pericardial effusion and cardiac tamponade, so the patient should be intubated and mechanically ventilated with the appropriate sedation.3, 11

CONCLUSION

Proposed algorithm for the prehospital management of aortic dissection is shown in Figure 1.
