Abstract

Background/Aim: Gliclazide is one of the most commonly prescribed oral anti-hyperglycaemic therapies in type 2 diabetes mellitus (T2D). Recently reported additional beneficial pharmacological properties of gliclazide, including immunomodulatory and anticoagulant activities, suggested its potential application in treatment of type 1 diabetes mellitus (T1D). However, following oral administration, gliclazide was shown to have poor and variable absorption directing research into development of novel pharmaceutical delivery systems of gliclazide suitable for T1D. Since bile acids have previously demonstrated stabilising and controlled-release effects on microcapsules, their use for preparation of microcapsules of gliclazide may lead to improvements in gliclazide release, absorption and anti-diabetic effects. This investigation was aimed to evaluate drug absorption profiles and hypoglycaemic effects of alginate-based microcapsules of gliclazide, prepared together with or without cholic acid, in healthy rats.

Methods: Thirty healthy Wistar rats with confirmed normal glucose blood concentration were allocated into five groups and administered with a single dose of either vehicle microcapsules, gliclazide in suspension, gliclazide microcapsules, gliclazide in suspension together with cholic acid or microencapsulated gliclazide in combination with cholic acid. Following respective gliclazide dose, blood was sampled over next 10 hours and blood glucose levels and gliclazide serum concentrations were measured.

Results: This analysis demonstrated altered effects of different gliclazide formulations in healthy rats with the highest gliclazide absorption mirrored by the most profound hypoglycaemic effect being achieved after its oral administration as a suspension (p <0.01) compared to any other investigated pharmaceutical formulation.

Conclusion: When conducting pharmacokinetic characterisation of novel pharmaceutical formulations of antidiabetic drugs, it is of utmost importance to select the appropriate research model and consider the possible role of gut-metabolic activation on their hypoglycaemic effects.

Key words: gliclazide; capsules; bile acids; hypoglycaemic agents; rats.

Introduction

Gliclazide, a second-generation sulphonylurea, is the second most commonly prescribed oral antihyperglycaemic agent in the treatment of type 2 diabetes mellitus (T2D), after metformin.1 It is the preferred therapeutic option because of its selective binding to the pancreatic β-cell sul-
phosphorylurea receptor (SUR1) and subsequent stimulation of insulin release, as well as for its unique antioxidant properties and other beneficial haematological effects. Furthermore, gliclazide was shown to restore peripheral insulin sensitivity, decrease hepatic glucose production and skeletal muscle glycogenesis, independent of its insulin-mediated effects. Due to its known extrapancreatic action, gliclazide may exert conceivable potential in type 1 diabetes mellitus (T1D) treatment, especially when used in combination with other agents that exhibit hypoglycaemic effects, including certain bile acids and probiotics, as previously reported.

Despite the clinical experience with gliclazide being extensive and its pharmacological and pharmaceutical applications well-documented, poor and variable absorption after oral administration has limited its potential applications in T1D due to the inconsistent dose-response effects, necessitating research into novel pharmaceutical delivery systems of gliclazide suitable for T1D. Therefore, besides available immediate and modified release formulations of gliclazide, novel pharmaceutical approaches that utilise high-scale techniques, such as drug microencapsulation are needed for enhancement of its oral absorption and potentially maintain tight blood glucose levels in diabetic patients.

Multiple recent studies reported on the development and characterisation of novel alginate-based microencapsulated formulations of gliclazide mixed with different bile acids. Notably, these new gliclazide formulations exhibited stable colon-targeted delivery and its enhanced pharmacokinetic and pharmacodynamics effects in T1D rats when cholic, deoxycholic or taurocholic acids were added to the microencapsulated gliclazide formulation.

However, given the novelty of the designed microencapsulated gliclazide formulations, basic in vivo pharmacokinetic and pharmacodynamic studies should be also conducted in a sufficient number of clinically healthy animals, in order to validate the in vitro and in silico approaches needed to gain a more comprehensive understanding of its efficacy and safety profiles in diabetic models and ultimately patients.

Hence, this study was aimed to investigate the hypoglycaemic effects of alginate-based microcapsules of gliclazide, prepared together with or without cholic acid, in healthy rats. Focusing on the effects of microencapsulation and addition of cholic acid on gliclazide systemic absorption in healthy animals, this study complements the ongoing work aimed at investigating potential bile acids use and microencapsulation technology in the delivery and absorption of antidiabetic agents.

Methods

Reagents and Materials
Gliclazide (99.9%), Na-alginate (98%), and cholic acid (95%) were supplied by Sigma Chemical Co, USA. Anhydrous calcium chloride was purchased from Scharlab S.L, Australia. The suspending gel for ultrasound-aided manipulation was obtained from Australian Medical Association, Perth, WA, Australia. Test tubes for oral gavage were purchased from Instech Laboratories, Inc., USA. Acetonitrile and HPLC-grade water were delivered by Fisher Chemical, Australia. All other chemical reagents and solvents were supplied by Merck, Australia.

Microcapsules Preparation
Fresh stock of gliclazide (40 mg/mL) and cholic acid (4 mg/mL) were prepared by dissolving the respective powders in 10 % ultrasonic suspending gel, while the 2 % CaCl₂ stock solution was prepared by adding CaCl₂ powder to HPLC-grade water. Each stock preparation was stored at 4° C and used within 12 hours. Sodium alginate-based microcapsules of gliclazide and cholic acid were prepared as previously described, according to the established protocols.

Animal Procedures and Blood Glucose Measurements
The conducted experiments were approved by the local Ethics Committee for Experimental Animals Welfare Protection of the University of Novi Sad, Serbia (approval number: 01-31/4-1/2014-01). All experiments were performed in alignment with ethical principles and guidelines for welfare of the laboratory animals. Male Wistar rats, 8-10 weeks old, were obtained from the Animal Farming Facility of the Military Medical Academy, Belgrade, Serbia and were allowed a 7-day acclimatization period before experimentation.
Results

Blood Glucose Measurements

According to the D'Agostino-Pearson omnibus test, data passed the normality test (p > 0.05), indicating normal distribution of data. All administered gliclazide formulations, with or without added cholic acid resulted in significantly lower blood glucose concentrations in healthy rats compared with control vehicle microcapsules, therefore indicating a strong and significant hypoglycaemic effects of orally administered gliclazide (Figure 1). However, the reduction in blood glucose levels was more profound (p < 0.01) compared with control group when rats were treated with gliclazide suspension than with gliclazide microcapsules (p<0.05). On the other hand, when cholic acid was added to gliclazide, microencapsulated combination of gliclazide and cholic acid exerted stronger hypoglycaemic effects compared to the combination administered in suspension.

Gliclazide Serum Concentrations Measurements

Gliclazide concentrations in serum were measured using high pressure liquid chromatography (HPLC) techniques based on the previously established methods. Shortly, 40 µL of serum samples were extracted with acetonitrile in a 2:1 ratio, vortexed for 30 seconds and centrifuged (10,000 rpm/min) for 5 minutes. The supernatant was injected into the HPLC system, together with respective standards and quality control samples and analysed in the same manner. The used HPLC system was HPLC-DAD (Dionex, USA) with ODS Hypersil analytical column (100 mm x 2.1 mm, 5 µm; 120 Å) from Agilent with the appropriate ODS precolumn (Agilent; 20 mm x 2.1 mm, 5 µm). The mobile phase was 49 % acetonitrile and 51 % water, v/v (pH 2.7). The flow rate was 0.4 mL/min, and the analysis was performed using the wavelength of 229 nm. Limit of detection (LOD) was 0.4 µg/mL, limit of quantification (LOQ) was 0.5 µg/mL, whereas the recovery of 85.83 ± 4.02% and linearity of 0.8 - 500 µg/mL was noted.

Statistical Analysis

The D'Agostino-Pearson omnibus test was used to test for the normality of data (p=0.05). Linear regression and one-way ANOVA analysis followed by a post hoc Tukey’s multiple comparison test was performed. Data are represented as mean ± standard deviation (SD). GraphPad Prism version 5.0 (GraphPad Software, Inc., USA) was used and p values reported where significant (p < 0.05) or highly significant (p < 0.01).
reach its peak concentration in serum ($T_{\text{max}}$) was significantly prolonged ($p < 0.05$) with microencapsulated gliclazide formulation versus gliclazide suspension, with $T_{\text{max}}$ values being $276.00 \pm 116.96$ minutes and $138.00 \pm 58.48$ min, respectively. Addition of cholic acid to gliclazide microcapsules resulted in significantly higher concentrations in serum compared to non-microencapsulated combination of gliclazide and respective bile acid ($p < 0.05$).

### Discussion

It has been previously shown that diabetes may influence the pharmacokinetic, as well as pharmacodynamic properties of various oral antidiabetic compounds, including gliclazide, presumably due to the pre-systemic drug elimination or altered gastric emptying and gastrointestinal motility in diabetic individuals.\(^{18, 19}\) In the present study, healthy rats exhibited increased gliclazide bioavailability compared to that previously reported in diabetic rats treated with same pharmaceutical gliclazide formulations,\(^{17}\) regardless of its administered formulation. However, Stětinová et al\(^{20}\) reported that even when biological gliclazide bioavailability was similar in both healthy and alloxan-induced diabetic animals, the hypoglycaemic effect of gliclazide was not equally distributed and was less pronounced in animals with alloxan-induced hyperglycaemia (23 % decrease at 60 min) compared to healthy animals (36 % decrease at 60 min). Interestingly, at later time points, this gliclazide hypoglycaemic effect was maintained in hyperglycaemic animals, while healthy animals demonstrated a reversal of the hypoglycaemic effect.\(^{20}\)

It was shown here that in healthy normoglycaemic animals, gliclazide microencapsulation resulted in its significantly lower $C_{\text{max}}$ and almost doubled $T_{\text{max}}$ values, compared with non-microencapsulated gliclazide. On the other hand, the addition of cholic acid into the alginate-based gliclazide microcapsules increased its serum concentrations and extended the time needed to reach its peak concentration in serum compared to the combination of gliclazide plus cholic acid that was not microencapsulated (Figure 2). Similar findings have previously been reported for alloxan-induced diabetic animals.\(^{17}\) This was also confirmed by the in vitro stability and release kinetic studies of the same gliclazide formulations, indicating possible suitability of microencapsulated gliclazide formulations for its sustained and targeted delivery to the lower intestine.\(^{12, 15}\)

Having a closer look at the maximum blood glucose level drops ($E_{\text{max}}$) compared to its initial values before gliclazide administration ($E_0$) in healthy rats, it was observed that gliclazide suspension lowered the glucose levels by 69 %, microencapsulated gliclazide formulation by 51 %, combination of gliclazide suspension and cholic acid by 46 % and microencapsulated combination of gliclazide and cholic acid by 46 %. Interestingly, in the previously reported study in diabetic rats,\(^{7}\) the greatest glucose levels reduction from the initial values was observed after the administration of the microencapsulated gliclazide and not with gliclazide suspension as it was the case in healthy rats. Moreover, even though statistical test showed non-significant difference between healthy and diabetic rats, a tendency towards higher values of $C_{\text{max}}$ and shorter $T_{\text{max}}$ for gliclazide were observed in healthy rats within this study compared with alloxan-induced diabetic rats from the previous study,\(^{17}\) regardless of the administered gliclazide pharmaceutical formulation.

Linear regression analysis of blood glucose levels throughout time and gliclazide concentrations in serum administered in different pharmaceutical formulations in healthy rats revealed disproportional association of gliclazide suspension treatment and resulting glucose levels in blood. Even
though gliclazide and cholic acid microcapsules also resulted in consistent reduction in blood glucose levels, these changes were not significantly different compared with control (Figure 3).

Mikov et al. have reported decreased bioavailability of gliclazide administered in suspension in alloxan-induced diabetic rats compared to healthy controls, possibly due to gastrointestinal motility disorder related to diabetes. However, in the same study, when gliclazide was administered together with sodium 3α,7α-dihydroxy-12-keto-5β-cholanate (MKC), its bioavailability was further increased in healthy animals, but no significant differences were observed in terms of glucose levels. On the other hand, gliclazide bioavailability being substantially lower in diabetic rats was not altered by this bile acid salt, but the hypoglycaemic action in diabetic rats of the combination of gliclazide and MKC was significantly greater in comparison to the situation when gliclazide was administered alone.

Differential drug permeation-enhancing and hypoglycaemic effects of various bile acids are further supported by a recently reported study that evaluated the glucose lowering potential of novel microencapsulated gliclazide pharmaceutical formulation with gliclazide alone or in combination with a taurocholic acid (TCA). Mathavan et al. reported that microencapsulated gliclazide alone failed to exert the hypoglycaemic effect in diabetic rats, whereas the addition of TCA into gliclazide microcapsules resulted in enhanced gliclazide absorption and significant hypoglycaemic effects compared with diabetic untreated controls. However, the data on the effects of this microencapsulated gliclazide formulation in healthy animals is not reported.

Another study that investigated pharmacokinetics and pharmacodynamics of gliclazide in immediate and modified release formulation tablets showed non-significant difference of evaluated parameters between healthy and streptozotocin-induced diabetic rats for either formulations. Even though the differences were not significant, a tendency towards slower elimination and higher mean residence time (MRT) in both healthy and diabetic rats treated with modified release gliclazide versus its immediate release formulation was found, confirming the sustained release mechanism of the modified release drug formulations. Resztak et al. also reported significantly higher reduction of blood glucose level with immediate-release gliclazide formulation than with one with modified release, with the highest pharmacodynamic efficacy of gliclazide being observed in the healthy animals following treatment with the immediate-release gliclazide tablets, whereas the hypoglycaemic effect of the drug was reduced in diabetic animals. Therefore, the authors suggested that hypoglycaemic effects of gliclazide in healthy subjects might not be a suitable approach for characterising antidiabetic drugs.

**Conclusion**

This study demonstrated the impact of gliclazide pharmaceutical formulations on the systemic absorption and hypoglycaemic effects in healthy rats, revealing that altered pharmacokinetic/pharmacodynamic effects were due to the modified physiological outcomes in alloxan-induced diabetic rats. The highest gliclazide absorption was achieved after its administration as a suspension and was mirrored by the most profound hypoglycaemic effect versus any other investigated pharmaceutical formulation, unlike in diabetic rats where gliclazide hypoglycaemic effects were found to be independent of its absorption and serum concentrations. Taken together, these data indicate the importance of selecting the appropriate model for pharmacokinetic characterisation of novel pharmaceutical formulations of antidiabetic drugs and the possible role of gut-metabolic activation on their hypoglycaemic effects.
