Onset Rate and Intensity of Signs of Organophosphate Poisoning Related to Paraoxon Dose and Survival in Rats

Žana M Maksimović,1, 2 Dajana Duka,3 Nataša Bednarčuk,3 Ranko Škrbić,2, 4 Miloš P Stojilković2, 4

Abstract

Introduction: Organophosphorus compounds (OP) bind to acetylcholinesterase (AChE) and inactivate it. In the synaptic cleft, undestroyed and accumulated acetylcholine produce the acute cholinergic effects. The aim of this study was to determine the frequency, speed of onset and intensity of certain signs of paraoxon poisoning depending on dose and outcome of poisoning.

Methods: The study was conducted in adult Wistar rats. The median lethal dose \( (LD_{50}) \) of paraoxon as well as protective ratio (PR) of atropine (10 mg/kg intramuscularly) was determined. Clinical signs of poisoning were observed: fasciculations, tremor, seizures, ataxia, piloerection, lacrimation, exophthalmos, bizarre/stereotypic behaviour and dyspnoea. The time from paraoxon injection to the first appearance of the sign of poisoning was recorded as well as the intensity of poisoning with evaluation at 10 time intervals throughout the 4 h observational period.

Results: The \( LD_{50} \) of paraoxon was 0.33 mg/kg (subcutaneously) and PR of atropine was 2.73. Dose-dependent, piloerection occurred more often \( (p = 0.009) \) and at higher intensity \( (p = 0.016) \) at higher doses. Fasciculations, tremor, seizures and ataxia occurred significantly earlier at higher doses of paraoxon \( (p = 0.015, 0.002, 0.021 \text{ and } 0.016, \text{ respectively}) \), as well as the intensity of seizure, tremor and fasciculation. Piloerection \( (p = 0.002) \) and seizures occurred more frequently \( (p = 0.009) \) in non-survivors. Fasciculations, tremor, seizures and ataxia occurred significantly earlier and at higher intensity in non-survivors \( (p < 0.001, \text{ for all parameters}) \), as well as dyspnoea \( (p = 0.009 \text{ and } p = 0.048) \). In atropine-protected rats, nicotinic effects persevered, so they were the prognostic parameter of the severity of the poisoning.

Conclusion: Seizures and fasciculations followed by tremor were strong prognostic parameters of the probability of lethal outcome of paraoxon poisoning. Also, the mentioned poisoning signs were with their intensity and speed of occurrence in a clear positive correlation with the administered dose of paraoxon. Even at high doses of paraoxon, atropine blocked the muscarinic (but not nicotinic) effects and somewhat mitigated the CNS toxic effects.

Keywords: Organophosphate; Acetylcholinesterase inhibitor; Paraoxon; Insecticide; Poisoning; Atropine.

Introduction

In the body, organophosphorus compound (OPC) binds to the serine group of the enzyme acetylcholinesterase (AChE, EC 3.1.1.7), phosphorylates it and creates a stable covalent bond...
Animals
The study was conducted in adult male and female Wistar rats, weighing 200-240 g, purchased from Faculty of Natural Sciences and Mathematics, University of Banja Luka, the Republic of Srpska. The animals had access to food and water ad libitum. The room temperature was maintained at 20-22 °C, with a 12 h light and dark cycle. The study was approved by Ethics Committee for the Protection and Welfare of Experimental Animals in Biomedical Research, Faculty of Medicine, University of Banja Luka (Decision No 18/1/20).

During the entire experiment, the “Guiding principles in the care of and use of laboratory animals” have been observed.

Chemicals
Paraoxon was purchased from Sigma Aldrich, St Louis, MO, USA. Application volume of the chemical was 1 mL/kg. Paraoxon was injected subcutaneously (sc) into the abdominal region, while atro-
pine was administered intramuscularly (im) into the right thigh. Stock solution of paraoxon (100 mg/mL) was dissolved in isopropyl alcohol. Final dilution for sc administration was made from saline (0.9 % NaCl) before injection. Atropine sulphate monohydrate was dissolved in saline up to the concentration of 10 mg/mL.

Study design
In these experiments, lethality of paraoxon and an antidote potential of atropine was based on the 24 h survival.

a) Paraoxon and saline
Increasing doses of paraoxon were administered sc. Each group consisted of 6 rats and doses were determined by the “up and down” method (doses were: 0.2, 0.3, 0.35, 0.4 mg/kg). One minute after paraoxon injection, rats were injected with 1 mL/kg saline im. Based on the 24 h lethality, median lethal dose (LD_{50}) was calculated.

b) Paraoxon and atropine
Increasing doses of paraoxon were administered sc (doses were: 0.6, 0.9, 1.2 mg/kg). Each group consisted of 6 rats and doses were determined by the “up and down” method. One minute after the injection of paraoxon, the rats were injected with 10 mg/kg of atropine im. The outcome was protective ratio (PR) ie, ratio of LD_{50} in protected and in unprotected rats.

c) Clinical signs of poisoning
The following clinical signs of poisoning were observed: fasciculations, tremor, seizures, ataxia, piloerection, lacrimation, exophthalmos, bizzare/stereotypic behaviour, dyspnoea. The time from paraoxon injection to the appearance of the sign of poisoning was recorded. The intensity of poisoning was recorded as: 0 - absent, 1 - mild / moderate, 2 - severe. Evaluation was performed in the 5th, 10th, 15th, 30th, 60th, 90th, 120th, 150th, 180th, 210th, and 240th minute. To analyse the intensity of symptoms throughout the observed period (4 h), ToxScore was introduced, as a parameter that summed the intensity of each sign in all time intervals. TotToxScore was a measure that represented the sum of all ToxScore for one animal.

Statistics
The LD_{50} values were computed by means of the Pharm/PCS statistical software, according to the Litchfield and Wilcoxon (1949).IBM SPSS 21.0 software was used for other statistical procedures. After the normality of data distribution was analysed (Kolmogorov–Smirnov test), the appropriate parametric / nonparametric test was used (Student t-test / Man-Whitney U test, One Way ANOVA / Kruskal-Wallis test) as well as Chi-Squared test for categorical data.

Results

Paraoxon
a) Dose
The LD_{50} of paraoxon was 0.33 mg/kg sc (95 % CI: 0.31 - 0.36). In all rats, death occurred in the first hour of poisoning (mean ± SD: 19.19 ± 6.19, 95 % CI: 16.37 - 22.01).

Fasciculations occurred in 85.71 % of all rats, piloerection in 50.00 %, exophthalmos in 95.23 %, lacrimation in 54.76 %, tremor in 97.62 %, seizures in 83.33 %, ataxia in 66.67 %, stereotypic behaviour in 69.05 % and dyspnoea in 26.19 % rats.

The frequency of symptoms at different doses of paraoxon was not significant, except in the case of piloerection, where it occurred after doses of paraoxon 0.2, 0.3, 0.35 and 0.4 mg/kg in 0 %, 33.33 %, 66.67 % and 75.00 %, respectively (χ^2 = 11,667, p = 0.009). The onset rate of poisoning clinical signs at different doses of paraoxon is shown in Table 1. Bizzare-stereotypic behaviour, although frequent (69.05 % of all animals), was not significantly different in either the intensity or the rate of sign on any parameter (data not shown).

Fasciculation, tremor, seizures, and ataxia occurred significantly earlier at higher doses of paraoxon. The intensity of signs measured 15 min and 4 h after paraoxon application relative to the dose applied is shown in Table 2. The time-point of 15th minute was taken as the time period when most of the signs of poisoning were manifested, yet most of the rats were still alive, and the time period of 4th hour was taken as the end of the observation period.

In the presented time intervals (15 min and 4 h after paraoxon), the intensity of seizures, tremor and fasciculations increased significantly with increasing doses. Piloerection was significantly

Figure 1: ToxScore for fasciculations and seizures relative to dose of paraoxon (Pox)

Figure 2: Mean ToxScore relative to dose of paraoxon (Pox)

TotToxScore is a measure that represents the sum of all ToxScores for one animal. TotToxScore values are shown in Figure 2. Although the difference was not statistically significant, an increase in the value of TotToxScore is noticeable, as a joint parameter of the intensity and duration of signs of poisoning, especially at high doses.

b) Survival

Analysing the frequency of clinical signs in relation to whether the rat survived or not, a significant difference was found regarding the piloerection: 23.81 % of survivors and 76.19 % of non-survivors had piloerection ($\chi^2 = 11.524, p = 0.002$). The same goes for seizure frequency (66.67 % in survivors vs 100.00 % in non-survivors have had seizures, $\chi^2 = 8,400, p = 0.009$). The speed of onset of clinical signs of poisoning relative to whether or not the animals survived is shown in Table 3. All signs of poisoning occurred earlier in non-survivors compared to survivors.

The intensity of the signs at 15 min after paraoxon application in relation to whether the rat survived...
The intensity of the signs persisted throughout the observation period. The intensities of certain symptoms at 15th min and after 4 h relative to the dose are shown in Table 6. The cross-section at the 15th minute was taken as the time period when most of the signs of poisoning were present, yet most of the rats were still alive, while the 4th h was taken as the end of the observation period.

ToO – time of occurrence (minutes after application of paraoxon) *Kruskal-Wallis test, **One-Way ANOVA. Red colour – statistically significant Values: mean ± standard deviation

The PR of atropine was 2.73 (LD$_{50}$ of paraoxon when atropine was administered 1 min after was 0.91 mg/kg sc (95% CI: 0.67 - 1.25)). In all rats, death occurred during the first hour of poisoning (mean ± SD: 14.00 ± 3.74, 95% CI: 10.87 - 17.13). Fasciculations occurred in 77.78% of all rats, piloerection in 33.33%, exophthalmos in 94.44%, lacrimation in 22.22%, tremor in 100.00%, seizures in 94.44%, ataxia in 44.44%, stereotypic behaviour in 38.89% and dyspnoea in 55.56% of rats.

In atropine-protected rats, the dose had a significantly smaller effect on the speed and frequency of symptoms. The frequency of any poisoning signs was not affected by the dose. As for the onset of clinical signs manifestation, a significant difference was found only in fasciculations ($p = 0.038$) and tremor ($p = 0.007$) (Table 5).

ToxScore, although without statistical significance, showed a clear increase in fasciculations, tremor, seizures, ataxia, and dyspnoea with increasing doses of paraoxon (Figure 3).

TotToxScore values for paraoxon poisoning followed by atropine administration are shown in Figure 4. Total Tox Score, although without statistical significance, showed a clear increase with higher dose.

**Discussion**

Paraoxon is one of the most toxic OPIs and is therefore banned from use as an insecticide in most countries. The obtained LD$_{50}$ of paraoxon was 0.33 mg/kg sc, which roughly corresponds to the data from the literature.\textsuperscript{17} Death in almost all animals occurs in the first two hours of OP
poisoning, which is consistent with the data obtained in this study.\(^\text{18}\)

The LD\(_{50}\) of paraoxon, when 10 mg/kg of atropine is administered after 1 minute, was 0.91, so the PR of atropine was 2.73, similar to the data in the literature.\(^\text{19}\) Atropine is used as an antidote for poisoning with AChE inhibitors. It is much more effective in carbamate poisoning than in those caused by OPCs.\(^\text{19}\) It is logical that PR will be significantly higher in carbamates than OP poisoning given that carbamates are reversible AChE inhibitors, so the spontaneous reactivation of AChE makes the task of atropine as an antidote less demanding.\(^\text{21-23}\) Considering the dose of atropine, 10 mg/kg im was selected because it is the most frequently used dose; therefore the results obtained in this experiments are comparable to the results of other researchers.\(^\text{24}\) Krutak-Kol and Domino tried different doses of atropine against paraoxon poisoning: 10, 33 and 100 mg/kg and found that higher doses did not increase survival. Moreover, a dose of 100 mg/kg was significantly less effective than the dose of 10 mg/kg.\(^\text{25}\) Repeated lower doses of atropine over time might potentially give better results.\(^\text{26}\)

The presence, time of occurrence and intensity of paraoxon poisoning signs were examined. The same parameters of poisoning were also observed at high lethal doses of paraoxon, in animals given atropine. Those signs that can be noticed only by observation without manipulation of the animal were analysed.

Lacrimation occurs by excessive stimulation of muscarinic receptors. Although not life-threatening, it can serve as a good indicator of muscarinic excitation, as well as sign of adequate atropinisation during treatment.\(^\text{3}\) Neither the intensity nor the rate of lacrimation occurred statistically significantly at different doses of paraoxon and in relation to the survival rate. However, when atropine was administered after paraoxon, lacrimation was significantly less common and occurred later, although significantly higher doses of paraoxon were administered (only 22 % vs 55 % when atropine was not administered). Regardless of the dose, the results obtained were expected since it is well known that atropine is an anti-muscarinic drug. The existence of lacrimation can indirectly indicate that there are other effects of muscarinic excitation (hypotension, bradycardia).

Muscarinic effects that are directly life-threatening are bronchoconstriction and bronchorrhea. Dyspnoea was monitored as a parameter indicating respiratory failure, which in studies by other researchers proved to be the main cause of lethality in OPI poisoning.\(^\text{27-29}\) The disadvantage of this study is that dyspnoea was only subjectively observed, without objective measuring of respiratory failure degree. Sometimes, in severe seizures dyspnoea could be noticed only when the intensity of seizures subsided. Nevertheless, a clear link was found in the intensity and speed of occurrence of dyspnoea in relation to whether the animal survived or not. In animals treated with atropine after paraoxon administration, atropine delayed and reduced the intensity of dyspnoea, although these were significantly higher doses of paraoxon. Houze et al analysed whether respiratory failure in OP poisoning was due to central or peripheral muscarinic effects.\(^\text{30}\) He showed that respiratory failure was almost completely corrected by atropine and not corrected at all by 100 times the equimolar dose of N-methylatropine and concluded that respiratory failure is due to central muscarinic effects. On the other hand, Villa et al found that 50 % and 75 % of LD\(_{50}\) paraoxon caused alterations in ventilation, but did not cause respiratory failure.\(^\text{31}\)

Fasciculations were a sign that, along with seizures, proved to be the most consistent parameter of the poisoning severity. Fasciculations occurred faster and were of higher intensity when the dose of paraoxon as well as survival of rats was observed. This can be explained by the fact that among the examined signs, fasciculations are those that follow overstimulation of nicotinic receptors on the neuromuscular junction. If it is assumed that according to the Poison Severity Score (PSS) in humans, any occurrence of nicotine sings of poisoning is considered at minimum as moderate poisoning, then it can be concluded that fasciculations, as a parameter of nicotine effects of poisoning, directly indicates the severity of poisoning.\(^\text{32}\) An additional problem is lack of effective antidote that would function as a nicotine antagonist, without serious side effects.\(^\text{33, 34}\) As expected, atropine administration did not affect the rate and intensity of fasciculations - they were of higher intensity and occurred earlier, because the dose of paraoxon was higher.

Muscle tremor was also a sign of inappropriate stimulation of nicotinic receptors on the neuro-
muscular joint; ie weakness of skeletal muscles. Tremor has been more often described in the literature as part of the delayed onset of extrapyramidal syndrome, rather than acute OP poisoning sign.\textsuperscript{35} Since the monitoring of poisoning signs was based on observation, tremor served as a good indicator of muscle weakness. A strong relationship was found between both the speed of onset and the intensity of tremor, and the dose of paraoxon or the lethal outcome in rats. As expected, the results did not change when atropine was given after paraoxon, but the tremor occurred earlier and was of stronger intensity at higher doses and in non-survivors.

ACh is also found in the preganglionic fibres of the sympathetic nervous system. Piloerection is a sign that occurs as a consequence of excessive stimulation of preganglionic nicotinic receptors of the sympathetic nervous system.\textsuperscript{36} Therefore, piloerection can be considered as potential predictor of sympathetic stimulation. The results of this study showed a strong relationship between the dose of paraoxon and the frequency of piloerection. Studies from other researchers show that the incidence of tachycardia in OP poisoning is 35-60 \%, making it more common than bradycardia.\textsuperscript{37} The alpha-1-adrenergic receptor, in addition to piloerection, in rats is also involved in retraction of the eyelids, leading to exophthalmos.\textsuperscript{38} Unlike piloerection, exophthalmos remained most persistent throughout the observed period and had no statistical significance in the intensity and rate of exophthalmos in relation to paraoxon dose and rat mortality. The same results were obtained when atropine was administered after high doses of paraoxon.

Seizures initially occur due to stimulation of cholinergic receptors in the CNS and at this stage can be reversed by atropine. Prolonged seizure activity is due to excessive release of glutamate, when atropine is not effective.\textsuperscript{39} For now, seizures are treated with combinations of anticholinergics and benzodiazepines but, given the role of glutamate in seizures, future therapies should include N-methyl-D-aspartate receptor (NMDA) antagonists.\textsuperscript{40} The rate and intensity of seizures were clearly correlated to dose and especially to death in paraoxon poisoning. Seizures occur significantly less frequently in OPI than in nerve agents.\textsuperscript{41} In this study, seizures occurred in 83 % of rats and 100 % of non-survivors, which additionally contribute to the characteristics of paraoxon as a nerve agents. Administration of atropine somewhat postponed and decreased the intensity of seizures. There was still a clear relationship between these parameters and paraoxon dose as well as fatal outcome, but seizures occurred later and were less intense than would be expected, given the paraoxon doses administered.

Ataxia is caused by stimulation of muscarinic receptors in the CNS. In addition, in acute OP poisoning, ataxia occurs as a consequence of muscle fatigue, but ataxia is more intense than would be expected from muscle fatigue alone.\textsuperscript{42} The results of this study show that ataxia occurred earlier at higher doses of paraoxon and in non-surviving rats.

ToxScore and TotToxScore are parameters that were introduced in order to see the persistence of symptoms related to the dose. Thus, the values of each sign in each point of time were summed, which made up the ToxScore, and the values of all ToxScores were added the calculate the TotToxScore for each animal. The pre-condition is that the animal survived the observation period. These parameters can also be used in future studies, when the protective effect of antidotes (either individually or in combination) can be compared, not only as a measure of survival, but also their ability to alleviate the signs of poisoning. ToxScore showed that the same parameters (seizure, fasciculation, tremor) that were significant indicators of the severity of poisoning lasted longer at higher doses. The TotToxScore had higher value at higher dose and, although the difference was not significant, showed a clear trend.

**Conclusion**

Seizures and fasciculations followed by tremor were strong prognostic parameters of the probability of lethal outcome of paraoxon poisoning. Also, the mentioned signs of poisoning were with their intensity and speed of occurrence in a clear correlation with the dose of paraoxon. Even at high doses of paraoxon, atropine blocked the muscarinic (but not nicotinic) effects, and somewhat mitigated the CNS effects.
