Preparing a Rat Brain Tissue Samples for Acetylcholinesterase Activity Measurement - the MM method

Sonja Marinković, Đorđe Đukanović, Nebojša Mandić-Kovačević, Tanja Cvjetković, Snežana Uletilović, Žana M Maksimović

Abstract

Background/Aim: Organophosphorus compounds (OP) bind to acetylcholinesterase (AChE) causing an irreversible inhibition of the enzyme. When doing in vivo studies of OP intoxication, to precisely measure AChE activity in the brain tissue it is necessary to remove as much blood from the brain as possible. By doing so, interference of the OPs present in the blood is avoided. Usually this demands expensive equipment, therefore, the aim of this study was to find a simple and economical method to eliminate the blood from brain blood vessels.

Methods: Wistar albino rats were divided into four groups named Control (C), Control washout (CW), Paraoxon (Pox) and Paraoxon washout (PoxW) group. Rats in Pox and PoxW were treated with 0.25 mg/kg paraoxon subcutaneously (sc), while C and CW received 1 mL/kg sc saline instead. The “Marinković-Maksimović” (“MM”) method was performed in rats from PoxW and CW groups. Activity of AChE was measured both in erythrocyte lysate and in brain tissue using spectrophotometry.

Results: Macroscopic examination revealed that the elimination of blood was achieved in CW and PoxW groups. Activity of AChE in homogenised brain tissue was expectedly lower in the Pox and PoxW group, when compared to C and CW group, respectively. The CW group had a lower value of AChE activity in the brain tissue compared to C group, while activity of AChE in the PoxW group was statistically higher than in the Pox group (p = 0.044).

Conclusion: The MM method provides good elimination of blood from the brain. Together with blood, present confounding factors that interfere with analysis in homogenised brain tissue were also eliminated.

Key words: Organophosphorus compounds; Oximes; Acetylcholinesterase; Enzyme activity; Rat brain.

Introduction

Organophosphorus compounds (OP) are synthetic compounds first synthesised in the 1930s, that are vastly used as pesticides, but also developed as warfare nerve agents. OP poisoning causes about 3,000,000 acute intoxications annually, 300,000 of which lead to fatalities. They bind to the serine group of acetylcholinesterase (AChE), form stable covalent bonds, making the enzyme inactive. The OP-AChE bond does not spontaneously dissociate, which is why OPs are called irreversible AChE inhibitors. Inactivated AChE cannot perform its function - the breakdown of acetylcholine (ACh) in the synaptic cleft. Accumulated ACh stimulates muscarinic and nicotinic
Experimental animals

Wistar albino rats, male and female, weighing between 260 - 350 g were used. The animals were housed 4 per cage, in air-conditioned rooms with controlled temperature (21 ± 1 °C) and a 12 h light/dark cycle. They had access to food and water ad libitum. For this study ethical approval was given by the Ethics Committee for the Protection and Welfare of Experimental Animals in Biomedical Research, Faculty of Medicine, University of Banja Luka (Decision No 18/1/20). During the entire experiment, the “Guiding principles in the care of and use of laboratory animals” have been observed.

Experimental protocol

To determine the efficacy of the circulatory perfusion method, rats were divided into 4 groups, 2 animals each. Groups were named Control (C), Paraoxon (Pox), Control with washout (CW) and Paraoxon with washout (PoxW). Rats in the Pox and PoxW group were treated with 0.25 mg/kg (0.25 mg/mL solution) paraoxon (Sigma Aldrich, St Louis, MO, USA) subcutaneously (sc), while C and CW groups received 1 mL/kg sc of saline instead. Half an hour later, rats were anaesthetised using 90 mg/kg ketamine and 10 mg/kg xylazine administered intraperitoneally (ip). The rat thoracic cavity was opened and blood samples were collected from the vena cava inferior into Lithium Heparin plasma tubes after which the animals were sacrificed via exsanguination. The “MM” method was performed in the rats from both PoxW and CW groups. Brains from both groups were excised, including cerebrum, cerebellum and the truncus encephali and stored at – 20 °C until homogenisation.

The “MM” method was performed in the rats from both PoxW and CW groups. Brains from both groups were excised, including cerebrum, cerebellum and the truncus encephali and stored at – 20 °C until homogenisation.

The Marinković-Maksimović method (MM method)

To access the rat heart and major blood vessels the rats were tied to operating boards 15 x 25 cm in size. A skin and muscle incision was made just below the processus xiphoideus using large surgical scissors. Next, bilateral incisions were made, following the medial axillary line. After separating the diaphragm from the anterior thoracic wall, the semi-attached anterior thoracic wall was clamped and put away to leave a clear operating field (Figure 1). To achieve exsanguination, inferior vena cava was cut just above the liver. Prior to the cannulation of the aorta, a 10 cm long thread was pulled under the ascending aorta. Using microscissors a small diameter incision (approx. 1-2 mm) was made in the anterior wall of the ascending aorta, just above the aortic root. The tip of the cannulation tube was then inserted into the lumen of the aorta, making sure that it does not surpass the point of the first aortic arch branch (Figure 2). Using the earlier prepared thread, the tube was tied into place. The abdominal aorta was clamped, to ensure that the saline used for washout goes only to the upper half of the body. Also, to achieve a free outflow of saline...
solution, *superior vena cava* was cut just above the heart. The upper body blood vessels were then perfused with a total of 100 mL of saline through the cannulation system, using 10 mL syringes (Figure 3). The efficiency of perfusion is observed during the procedure itself by observing the eyeballs of rats - pallor indicates the elimination of blood from the blood vessels of the eye (Figure 4).

### Tissue homogenisation and measuring of the AChE activity

The right side *cerebrum, cerebellum* and *truncus encephali*, priorly frozen at -20 °C were cut into smaller tissue fragments and weighted. Fragments were then mixed with phosphate buffer (0.1 M, pH 8.0) in a 1:20 ratio and homogenised at 10,000 rpm for 1 minute. Cold chain was main-
tained during the whole procedure. Homogenised tissue was centrifuged at 4 °C, for 15 minutes at 15,000 rpm and the supernatant was used as a sample for determining AChE activity in the brain tissue.

The AChE activity was measured by the Ellman colorimetric method using a Shimadzu UV-1800 spectrophotometer (Kyoto, Japan) and UV Probe 2.17 software (Kyoto, Japan).12 Activity was determined from the brain tissue samples and from blood samples (erythrocyte lysate). Activity of AChE in erythrocyte lysate was expressed as µmol/min/mL, while its activity in the brain tissue was expressed as µmol/min/g.

**Statistical analysis**

Normality of data was analysed and confirmed by Kolmogorov-Smirnov test. Appropriate parametric test was performed (Student t-test). Data were shown as mean values with their standard deviations (SD). Statistical significance was set at p < 0.05. IBM SPSS version 23.0 for Windows software was used for data analysis.

**Results**

Macroscopic examination of the brain indicated that good elimination of blood from brain tissue was achieved by washout (Figure 5).

[Figure 5: Macroscopic results of the “MM” method. The macroscopic difference in appearance of the rat brain from the control group (A) and from the control with washout group (B)]

Detailed values of weight, brain weight and AChE activity for each experimental animal are given in Table 1.

No significant difference in mean values of rat brain mass between groups with and without washout was found (t = 2.29, p = 0.262). There was no significant difference between mean values of AChE activity in erythrocytes between C and CW group (Student t-test: t = 0.88, p = 0.472), as well as between Pox and PoxW group (t = 0.45, p = 0.708) (Figure 6).

*There was significant difference between AChE activity in rat brain between Pox and PoxW group (Student t-test: t = 5.00, p = 0.044).
There was no significant difference between mean values of AChE activity in rat brain between C and CW group (Student t-test: t = 0.52, p = 0.655), but there was significant difference between Pox and PoxW group (t = 5.00, p = 0.044) (Figure 7).

Discussion

When analysing the AChE activity in brains of rats poisoned with OP and treated with oximes, the presence of blood in the brain can distort the results for several reasons, primarily due to lipophilicity of OPs and poor penetration of oximes through the BBB. Following absorption, OPs accumulate rapidly in fat, liver, kidneys and salivary glands. Lipophilic OPs are released more slowly from adipose tissue and have a milder acute but prolonged effect. When the applied oxime reactivates AChE, the leakage of lipophilic OPs from the depot re-inhibits AChE. Paraoxon (diethyl (4-nitrophenyl) phosphate) is the active metabolite of the OP insecticide parathion. The phosphorothioates (P=S) (eg, diazinon, parathion) are more lipophilic than phosphates (P=O) (eg, dichlorvos, paraoxon). Spontaneous reactivation of dimethyl-phosphorylated AChE often occurs rapidly even without oxime therapy. There is no such expectation for AChE inhibited with diethyl phosphoryl insecticides.5

How to increase therapeutic potential of oxime, by improving their BBB penetration remains a challenge in modern toxicology. As a very selectively permeable membrane, the BBB imposes several limitations for oxime penetration to the brain tissue, such as hydrophilicity, polarity and molecule size. Consequently, pyridinium aldoximes (PyAls) such as pralidoxime (2-PAM) have a very low rate of BBB penetration,14,15 which is mostly associated with their high hydrophilicity10 and permanent cationic charge. 2-PAM, which is most commonly used oxime in the treatment of OP poisonings, has a relatively low level of transport through the BBB.15,17

Respiratory failure has been identified in numerous studies as the leading cause of death in OP poisoning.16-28 Houze et al21 have shown that respiratory failure is most likely the result of central respiratory depression, rather than peripheral bronchoconstriction, bronchorrhoea and respiratory muscle fatigue.8,9 Knowing that, a crucial point in therapy would be reactivation of AChE in brain tissue.15 Because of that, non-quaternary organic compounds are introduced as novel antidotes in OP poisoning.22,23 Not having a quaternary group gives them a better penetrability through the BBB. Data from the literature indicate that the chlorine atoms in the oxime increase its lipophilicity.24 In OP insecticides, it has been shown that oximes with a functional group at the position 4 re-activate OP insecticides most effectively. Oximes with a bis-quaternary structure are more efficient than those ones with mono-quaternary structure. It is best that linker has 3-5 C-C connections. The double bond in the linker increases both their efficiency and toxicity.25,26

There are several ways to determine the efficiency of brain AChE reactivation by oximes, but most widely used is an indirect method. With this method the level of BBB of an oxime penetration is measured by the level of AChE reactivation in the brain tissue. To achieve precise results, it is necessary to remove blood from the brain. This way OPs present in the blood will not interfere with the results. Washing out blood from the brain by using the “MM” procedure, showed reduced detected AChE activity in homogenised brain tissue, which resulted in 0.15 µmol/min/g difference between control groups (C and CW). This decrease was due to the removing of the AChE present in red blood cells, whose activity could be measured in the brain homogenate in the absence of washing out. In both groups treated with paraoxon AChE activity was expectedly lower when compared with controls (37.24 % drop when comparing C and Pox group and 21.37 % difference between CW and PoxW). Comparing the results between Pox and PoxW group, AChE activity has remained higher in the PoxW group that was subjected to the “MM” procedure. Evidently the washout prevented remaining paraoxon from blood to bind with AChE and thus to distort the level of AChE activity in the brain after homogenisation.

By introducing the “MM” method, few things were tried to be avoided; one of them is that OP re-arrives from the blood into the brain to re-inhibit the AChE, thus obtaining lower values of AChE activity than the real ones. On the other hand, a new oxime that would penetrate BBB better could re-activate AChE in the brain. The presence of blood in homogenates would call into question
the origin of reactivated AChE - by eliminating the blood, the obtained values of AChE activity are those from the brain and not from the blood and brain.

Conclusion

The “MM” method provides good elimination of blood from the rat brain and thus eliminates confounding factors in the analysis of parameters from brain homogenates. The introduction of the procedure in the Centre for Biomedical Research, Faculty of Medicine, University of Banja Luka enables the universality of the procedure and the reproducibility of the results.

Acknowledgements

We would like to thank the Centre for Biomedical Research, Medical Faculty, University of Banja Luka, for providing us with the space, equipment and experimental animals. We would also like to thank Professor Rajko Igic, for sending to us the plastic tubing without whom the method would not have been possible.

Conflict of interest

The authors declare that there are no conflicts of interest. This study is partially funded by the Ministry of Scientific and Technological Development, Higher Education and Informational Society of the Government of the Republic of Srpska (Grant No 125 7030).
